**Abstract**—Recommender systems perform suggestions for items that might interest the users. The recommendation process is usually performed at the level of a single item, i.e., for each item not evaluated by a user, classic approaches look for the rating given by similar users for that item, or for an item with similar content. This leads to the so-called *overspecialization/serendipity problem*, in which the recommended items are trivial and users do not come across surprising items. In this paper we first show that the preferences of the users are actually distributed over a small set of classes of items, leading the recommended items to be too similar to the ones already evaluated. We also present a novel representation model, named *Class Path Information (CPI)*, able to express the current and future preferences of the users in terms of a ranked set of classes of items. Our approach to user preferences modeling is based on a semantic analysis of the items evaluated by the users, in order to extend the ground truth and predict where the future preferences of the users will go. Experimental results show that our approach, by including in the *CPI* model the same classes predicted by a state-of-the-art recommender system, is able to accurately model the preferences of the users in terms of classes and not in terms of single items, allowing recommender systems to suggest non trivial items.

**Keywords**—Recommender Systems; Semantic Analysis; User Modeling; Serendipity; Novelty

## I. INTRODUCTION

A recommender system suggests items that might be interesting for a user. In order to identify which items are useful for her/him, a recommender system has to *predict* that an item is worth recommending [1]. Rating prediction has been highlighted in the literature as the core recommendation task [1], [2], [3], its relevance has been further evidenced by the Netflix prize [4], and recent studies showed its effectiveness also in improving classification tasks [5], [6], [7], [8]. However, there are widely-known problems in the recommendation process.

**Overspecialization/Serendipity.** Independently from the approach used to build the predictions, recommender systems usually suggest items that have a strong similarity with the user profile, consequently the user always receives recommendations for items very similar to those that she/he already considered and never receives suggestions for unexpected, surprising, and novel items. This recommender systems limit, known in the literature as *overspecialization/serendipity problem*, worsens the user experience and does not give the users the opportunity to explore new items and to improve their knowledge [9]. It is known that this problem affects both the most used recommendation strategies, i.e., the content-based [10] and the collaborative filtering approaches [11]. In

fact, on the one hand content-based recommender systems build their predictions by calculating the similarity between the items' content, while on the other hand collaborative filtering looks for items evaluated by the users similar to the target user who has to receive the recommendations. In the literature, several researches also highlight that the serendipity of a resource can be computed by measuring its distance from the items previously considered by the target user [10], [9], [12], [13].

**Preference stability.** To complicate the previous scenario, there are domains like movies in which the preferences tend to be stable over time [14] (i.e., users tend to watch movies of the same genres or by the same director/actor). This is useful to maintain high-quality knowledge sources, but does not allow a system to diversify the recommendations. Preference stability leads also to the fact that when users get in touch with diverse items, diversity is not valued [15]. On the one side, users tend to access to agreeable information (a phenomenon known as *filter bubble* [16]) and this lead to the overspecialization problem, while on the other side they do not want to face diversity.

**Our contributions.** In this paper we want to address the following research question: *can we exploit user preferences and represent them in a broader way, in order to suggest non trivial items, but not too diverse from those the user already evaluated?* In order to face this problem, we present a representation model, named *Class Path Information (CPI)*, built as a ranking of the classes of items that each user prefers. The *CPI* model is built with a novel approach that performs a semantic analysis of the items already evaluated by a user, in order to extend the ground truth and infer if the terms used to describe the items evaluated by a user that belong to a class (e.g., the movies of a specific genre) also characterize other classes of items, which the user may have or may have not evaluated. By modeling user preferences in terms of classes and by predicting where the future preferences of the users will go, a recommender system can generate serendipity without recommending to the users something too far from their preferences. Moreover, by understanding the context in which recommendations should be produced in terms of classes, we avoid calculating the semantic distance between single items, which is a heavy process in terms of computational costs. Another advantage offered by this approach is that the generated models can be used to produce recommendations with any approach. Indeed, the *CPI* provides information of the classes of items the user prefers, which can be exploited

by any recommendation technique.

The main contributions coming from our proposal are the following:

- we show that preference stability exists in terms of classes of items. An analysis performed on two real-world datasets shows that user preferences are distributed over a small set of classes;
- we characterize each class of items using a set of *Semantic Binary Sieves* (SBS), a novel type of filter able to weigh the relevance of each class for each user;
- we develop an algorithm able to evaluate a relevance score of each class of items for each user by using the *SBS* filters;
- we introduce the novel concept of *Class Path Information* (CPI) model, which builds a relevance score of the classes of items each user prefers, and define an algorithm to create it;
- we evaluate our approach on a real-world dataset and show that the classes available in the model have a large overlap with those of the items predicted by a state-of-the-art recommender system.

**Roadmap.** The rest of the paper is organized as follows: Section II provides a background on the concepts handled by our proposal and the formal definition of our problem; Section III presents an analysis of preference stability on two real-world datasets; Section IV describes the details of the proposed approach to model user preferences in terms of classes; Section V describes the experimental framework used to evaluate our proposal; Section VI discusses related work; Section VII contains conclusions and future work.

## II. PRELIMINARIES

**Background.** For many years the item descriptions were analyzed with a word vector space model, where all the terms of each item description are processed by TF-IDF [17] and stored in a weighted vector of terms. Due to the fact that this approach based on a simple *bag of words* is not able to perform a semantic disambiguation of the words in an item description, and motivated by the fact that exploiting a taxonomy for categorization purposes is an approach recognized in the literature [18] and by the fact that semantic analysis is useful to improve the accuracy of a classification [19], [20], we decided to exploit the functionalities offered by the WordNet environment. Wordnet is a large lexical database of English, where *nouns*, *verbs*, *adjectives* and *adverbs* are grouped into sets of cognitive synonyms (synsets), each expressing a distinct concept. Synsets are interlinked by means of conceptual-semantic and lexical relations. Wordnet currently contains about 155,287 words, organized into 117,659 synsets for a total of 206,941 word-sense pairs [21]. In a short, the main relation among words in WordNet is the synonymy and the synsets are unordered sets of grouped words that denote the same concept and are interchangeable in many contexts. Each synset is linked to other synsets through a small number of *conceptual relations*. Word forms with several distinct meanings are represented in as many distinct synsets, in this way each form-meaning pair in WordNet will be unique

(e.g. the *fly* insect and the *fly* verb belong to two distinct synsets). Most of the WordNet relations connect words that belong to the same part-of-speech (POS). There are four POS: *nouns*, *verbs*, *adjectives* and *adverbs*. Both nouns and verbs are organized into precise hierarchies, defined by hypernym or *is-a* relationships. For example, the first sense of the word *radio* would have the following hypernym hierarchy, where the words at the same level are synonyms of each other: some sense of *radio* is synonymous with some other senses of *radiocommunication* or *wireless*, and so on. Each synset has a unique index and shares its properties, such as a gloss or dictionary definition. We use the synsets to perform both the definition of binary filters and the evaluation of the relevance scores of the classes in a user profile.

**Notation.** We are given a set of users  $U = \{u_1, \dots, u_N\}$ , a set of items  $I = \{i_1, \dots, i_M\}$ , and a set  $V$  of values used to express the user preferences (e.g.,  $V = [1, 5]$  or  $V = \{like, dislike\}$ ). The set of all possible preferences expressed by the users is a ternary relation  $P \subseteq U \times I \times V$ . We denote as  $P_+ \subseteq P$  the subset of preferences with a positive value (i.e.,  $P_+ = \{(u, i, v) \in P | v \geq \bar{v} \vee v = like\}$ ), where  $\bar{v}$  indicates the mean value (in the previous example,  $\bar{v} = 3$ ). Moreover, we denote as  $I_+ = \{i \in I | \exists (u, i, v) \in P_+\}$  the set of items for which there is a positive preference, and as  $I_u = \{i \in I | \exists (u, i, v) \in P_+ \wedge u \in U\}$  the set of items a user  $u$  likes. Let  $C = \{c_1, \dots, c_K\}$  be a set of classes used to classify the items; we denote as  $C_i \subseteq C$  the set of classes used to classify an item  $i$  (e.g.,  $C_i$  might be the set of genres that a movie  $i$  was classified with), and with  $C_u = \{c \in C | \exists (u, i, v) \in P_+ \wedge i \in C_i\}$  the classes associated to the items that a user likes.

Let  $BoW = \{t_1, \dots, t_W\}$  be the bag of words used to describe the items in  $I$ ; we denote as  $d_i$  be the binary vector used to describe each item  $i \in I$  (each vector is such that  $|d_i| = |BoW|$ ). We define as  $S = \{s_1, \dots, s_W\}$  the set of synsets associated to  $BoW$  (that is, for each term used to describe an item, we consider its associated synset), and as  $sd_i$  the semantic description of  $i$ . The set of semantic descriptions is denoted as  $D = \{sd_1, \dots, sd_M\}$  (note that we have a semantic description for each item, so  $|D| = |I|$ ). The approach used to extract  $sd_i$  from  $d_i$  is described in detail in Section IV.

**Problem Definition.** Given a set of positive preferences  $P_+$  that characterizes the items each user likes, a set of classes  $C$  used to classify the items, and a set of semantic descriptions  $D$ , our goal is to assign a relevance score  $r_u(c)$  for each user  $u$  and each class  $c$ , based on the semantic descriptions  $D$ . Each relevance score will be combined into a model  $CPI_u$ , defined as follows:

$$CPI_u = (r_u(c_1), \dots, r_u(c_K)) \quad (1)$$

Each  $CPI_u$  must respect the following properties:

- $r_u(c_1) \geq \dots \geq r_u(c_K)$
- $CPI_u \supseteq C_u$

So, each  $CPI$  model contains a list of classes ranked by relevance score and the classes available in the model are a superset of the classes for which a user expressed a preference

TABLE I: Yahoo! Webscope R4 Genres

(i.e., we are going to predict the future preferences of the users, based on the semantic analysis of the items she/he likes).

### III. CHARACTERIZING PREFERENCE STABILITY

In order to understand if preference stability can be characterized in terms of the classes used to classify the items, in this section we are going to present the distribution of the classes  $C_u$  related to the items a user likes. For each user  $u \in U$  and each class  $c \in C_u$ , we consider how many positive preferences the user expressed for that class. We call this value the *popularity* of the class for that user, and define it as the percentage of items that the user likes and belong to that class:

$$popularity(u, c) = \frac{|\{(u, i, v) \in P_+ | i \in c\}|}{|\{(u, i, v) \in P_+\}|} \quad (2)$$

Then, we ordered the *popularity* values of each user in decreasing order and average all the *popularity* values at the position  $j$  in the list of each user (i.e., if  $j = 1$ , we calculate the average amount of preferences each user expressed for the items in the most popular class).

The study has been performed on the following real-world datasets:

**Yahoo! Webscope R4**<sup>1</sup>. The dataset contains a large amount of data related to users preferences expressed on the Yahoo! Movies community that are rated on the base of two different scales, from 1 to 13 and from 1 to 5 (we have chosen to use the latter). The training data is composed by 7,642 users ( $|U|$ ), 11,915 movies/items ( $|I|$ ), and 211,231 ratings ( $|R|$ ), and all users involved have rated at least 10 items and all items are rated by at least one user. The test data is composed by 2,309 users, 2,380 items, and 10,136 ratings. There are no test users/items that do not also appear in the training data. Each user in the training and test data is represented by a unique ID. As shown in Table I, the items are classified by Yahoo in 20 different classes (movie genres), and it should be noted that each item may be classified in multiple classes.

**Movielens 10M**<sup>2</sup>. This dataset contains 10,000,054 ratings and 95,580 tags related to 10,681 movies by 71,567 users that were selected at random from MovieLens (a movie recommendation website). All the users in the dataset had rated at least

TABLE II: Movielens 10M Genres

Class	Genre	Class	Genre
01	Action	10	Film-Noir
02	Adventure	11	Horror
03	Animation	12	Musical
04	Children's	13	Mystery
05	Comedy	14	Romance
06	Crime	15	Sci-Fi
07	Documentary	16	Thriller
08	Drama	17	War
09	Fantasy	18	Western

Fig. 1: Webscope-R4 - Involved Classes in the User Preferences

20 movies, and each user is represented by a unique ID. The ratings of the items are based on a 5-star scale, with *half-star* increments. As shown in Table II, in this dataset the items are classified by Movielens in 18 different classes (movie genres), and it is should be noted that also in this case each item may be classified in multiple classes.

Fig. 1 and Fig. 2 show the distribution of the popularities for the Yahoo! Webscope R4 and the Movielens 10M datasets. In Fig. 1, we can see that 41% of the preferences are all in a single class (in other words, nearly half of the positive ratings that the users give are for the same genre of movies) and, by considering as characterizing only the classes with *popularity*  $\geq 1\%$  (represented by the  $\Delta$  area), it is possible to observe that user preferences are distributed on 6 out of 20 classes. Fig. 2 shows that in the Movielens dataset preference stability has a lower impact. In fact, 26% of the ratings are in the most important class for each user, and 10 out of 18 classes are involved in the user preferences.

This analysis showed that preferences stability exists in terms of classes, and that user preferences are distributed between 30% and 55% of the classes. Based on these results, in the next section we are going to deepen our knowledge on the user preferences in terms of classes, in order to accurately model them.

## IV. OUR APPROACH

In this section we present our approach, which performs a semantic analysis of the descriptions of the items the users like, in order to build a model that infers where the future preferences will go. The goal is to understand which terms

<sup>1</sup><http://webscope.sandbox.yahoo.com>

<sup>2</sup><http://grouplens.org/datasets/movielens/>

Fig. 2: Movielens 10M - Involved Classes in the User Preferences

used to describe an item that a user likes characterize other classes of items. Our modeling approach performs four steps:

- 1) **Text Preprocessing:** processing of the textual information (description, title, etc.) present in all items, in order to remove the useless elements for the subsequent operation of synset retrieving;
- 2) **User Modeling:** creation of a model that contains which synsets are present in the items a user likes;
- 3) **Semantic Binary Sieve Construction:** creation of a *binary vector* for each class of items, and subsequent definition of the *Semantic Binary Sieves* (SBS), a series of filters that we use to estimate which synsets are relevant for that class;
- 4) **Class Path Information Modeling:** definition of the *Class Path Information* (CPI) model that, based on the semantic analyses performed in the previous steps, infers the user preferences in terms of classes.

Note that all steps are based on the use of WordNet synsets, which allows us to consider the semantics of the content, without performing complex operations on it. In the following, we will describe in detail how each step works.

#### A. Text Preprocessing

Before extracting the WordNet synsets from the text that describes each item, we need to follow several preprocessing steps. The first step is to detect the correct *Part-Of-Speech* (POS) for each word in the text; in order to perform this task, we used the *Stanford Log-linear Part-Of-Speech Tagger* [22]. In the second step we remove punctuation marks and *stop-words*, which represent noise during the semantic analysis. Several *stop-words* lists can be found in the Internet, and in this work we used a list of 429 *stop-words* made available with the *Onix Text Retrieval Toolkit*<sup>3</sup>. In the third step, after we have determined the lemma of each word using the Java API implementation for WordNet Searching JAWS<sup>4</sup>, we perform the so-called word sense disambiguation, a process where the correct sense of each word is determined. The best sense of each word in a sentence was found using the Java

<sup>3</sup><http://www.lextek.com/manuals/onix/stopwords.html>

<sup>4</sup><http://lyle.smu.edu/tspell/jaws/index.html>

implementation of the adapted Lesk algorithm provided by the *Denmark Technical University* similarity application [23]. All the collected synsets form the set  $S = \{s_1, \dots, s_W\}$  defined in Section II. The output of this step is the semantic disambiguation of the textual description of each item  $i \in I$ , which is stored in a binary vector  $ds_i$ ; each element of the vector  $ds_i[w]$  is 1 if the corresponding synset appears in the item description, and 0 otherwise.

#### B. User Modeling

For each user  $u \in U$ , this step considers the set of items  $I_u$  she/he likes, and builds a user model  $m_u$  that describes which synsets characterize the user profile (i.e., which synsets appear in the semantic description of these items). Each model  $m_u$  is a binary vector that contains an element for each synset  $s_w \in S$ .

In order to build the vector, we consider the semantic description  $ds_i$  of each item  $i \in I_u$  for which the user expressed a positive preference. This step builds  $m_u$ , by performing the following operation on each element  $w$ :

$$m_u[w] = \begin{cases} 1, & \text{if } ds_i[w] = 1 \\ m_u[w], & \text{otherwise} \end{cases} \quad (3)$$

This means that if the semantic description of an item  $i$  contains the synset  $s_w$ , the synset becomes relevant for the user, and we set to 1 the bit at position  $w$  in the user model  $m_u$ ; otherwise, its value remains unaltered. By performing this operation for all the items  $i \in I_u$ , we model which synsets are relevant for the user. The output of this step is a set  $M = \{m_1, \dots, m_N\}$  of user models (note that we have a model for each user, so  $|M| = |U|$ ).

#### C. Semantic Binary Sieve Construction

For each class  $c \in C$ , we create a binary vector that will store which synsets are relevant for that class. These vectors, called *Semantic Binary Sieves*, will be stored in a set  $B = \{b_1, \dots, b_K\}$  (note that  $|B| = |C|$ , since we have a vector for each class). Each vector  $b_k \in B$  contains an element for each synset  $s_w \in S$  (i.e.,  $|b_k| = |S|$ ).

In order to build the vector, we consider the semantic description  $ds_i$  of each item  $i \in I_+$  for which there is a positive preference, and each class  $c_k$  with whom  $i$  was classified. The binary vector  $b_k$  will store which synsets are relevant for a class  $c_k$ , by performing the following operation on each element  $b_k[w]$  of the vector:

$$b_k[w] = \begin{cases} 1, & \text{if } ds_i[w] = 1 \wedge i \in c_k \\ b_k[w], & \text{otherwise} \end{cases} \quad (4)$$

In other words, if the semantic description of an item  $i$  contains the synset  $s_w$ , the synset becomes relevant for each class  $c_k$  that classifies  $i$ , and the semantic binary sieve  $b_k$  associated to  $c_k$  has the bit at position  $w$  set to 1; otherwise, its value remains unaltered. By performing this operation for all the items  $i \in I_+$  that are classified with  $c_k$ , we know which synsets are relevant for the class.

#### D. Class Path Information Modeling

This step compares the output of the two previous steps (i.e., the set  $B$  of binary vectors related to the *Semantic Binary Sieves*, and the set  $M$  of binary vectors related to the *user models*), in order to infer which classes are relevant for a user and where the future user preferences will go. The main idea is to consider which synsets are relevant for a user  $u$  (this information is stored in the user model  $m_u$ ) and evaluate which classes are characterized by the synsets in  $m_u$  (this information is contained in each vector  $b_k$ , which contains that synsets are relevant for the class  $c_k$ ). The objective is to build a relevance score  $r_u[k]$ , which indicates the relevance of the class  $c_k$  for the user  $u$ .

The key concept behind this step is that *we do not consider the items a user evaluated anymore*. Each vector in  $B$  is used as a filter (for this reason the vectors are called *semantic binary sieves*), which allows us to estimate the relevance of each class for that user. Therefore, the relevance score of a class for a user can be used to infer where the future preferences of the users will go, since *a user might be associated to classes of items she/he never expressed a preference for, but characterized by synsets that also characterize the user model*. By ordering the relevance scores in decreasing order (from the most to the least relevant), we can build a model, named *Class Path Information (CPI)*, which can be used to build recommendations for the users. Indeed, a recommender system might use this model to know which classes are relevant for the user, and with which score.

By considering each semantic binary sieve  $b_k \in B$  associated to the class  $c_k$  and the user model  $m_u$ , we define a matching criteria  $\Theta$  between each synset  $m_u[w]$  in the user model, and the corresponding synset  $b_k[w]$  in the semantic binary sieve, by adding 1 to the relevance score of that class for the user (element  $r_u[k]$ ) if the synset is set to 1 both in the semantic binary sieve and in the user model, and leaving the current value as it is otherwise. The semantic of the operator is shown in Equation (5).

$$b_k[w]\Theta m_u[w] = \begin{cases} r_u[k] + 1, & \text{if } m_u[w] = 1 \wedge b_k[w] = 1 \\ r_u[k], & \text{otherwise} \end{cases} \quad (5)$$

By comparing a user model  $m_u$  with each vector  $b_k \in B$ , we obtain a vector  $r_u$  that contains the relevance score of each class for the user (i.e.,  $|r_u| = |C|$ ). The relevance scores of each class for each user are sorted in decreasing order to build the *CPI* model for a user  $u$  (i.e., each model respects the following property:  $r_u(c_1) \geq \dots \geq r_u(c_K)$ ):

$$CPI_u = (r_u(c_1), \dots, r_u(c_K)) \quad (6)$$

The output of this step is a Class Path Information model  $CPI_u$  for each user  $u \in U$ .

#### V. EXPERIMENTAL FRAMEWORK

The experimental framework was developed by using a machine with an Intel Pentium CPU P6100 Dual Core (2 GHz  $\times$  2) and a Linux 64-bit Operating System (Debian Wheezy)

with 4 GBytes of RAM. The environment for this work is based on the Java language, with the support of Java API implementation for WordNet Searching (JAWS) to perform the semantic measures, and the support of Apache Mahout<sup>5</sup> Java framework to implement the state-of-the-art approach that we compare our CPI modeling approach with.

This section first describes the dataset and the preprocessing performed on the data, then we describe the strategy used to perform the evaluation, the metrics, and we conclude by presenting the experimental results.

##### A. Dataset and Data Preprocessing

We performed our experiments using the Yahoo! Webscope Movie dataset (R4) described in Section III. Note that we had to limit our evaluation only to one of the two datasets previously considered, since the Movielens 10M dataset does not contain any textual description of the items.

In order to create a binary sieve for each class used to build a CPI model for every user (we take in account only the 2,309 users available in the test set), we need to define an ontology of synsets based on the descriptions of the items. To perform this operation we considered the description and title of each movie, and since the used algorithm takes into account only the items with a rating above the average, we selected only the movies with a rating  $\geq 3$ .

##### B. Strategy

The objective of our approach is to create a model that infers the preferences of the users in terms of classes, not only relying on the ground truth. As stated in the motivation of our work, the main domain of application that could benefit of this modeling approach are the recommender systems, which build predictions for the items not yet evaluated. Therefore, we applied a state-of-the-art recommender system to our dataset, and evaluated for each user  $u$  the set of classes  $C_u$  for which a positive value was predicted, and compared them with the  $CPI_u$  model built for that user.

The system chosen for the comparison is SVD++ [24], the Koren's version of SVD [25] that has been proved to be one of the most accurate approaches. The SVD++ approach, which we implemented through the Mahout functionalities, in addition to the training dataset requires two additional parameters: the number of target features and the number of training steps to run. After a training of the parameters, the algorithm was run with the following setting: the first parameter would be equivalent to the number of involved genres, thus we have set this value to 20; about the second parameter, considering that larger values mean longer training time, and that we have not experienced significant improvements with higher values, we have chosen the value of 4.

We required the system to produce  $N$  recommendations for each user and tested different values of the parameter (more specifically,  $N = \{20, 40, \dots, 100\}$ ). The classes involved in the recommended items were almost identical in all the settings, therefore we chose  $N = 100$  to perform an evaluation in which as much information as possible was available for the comparison.

<sup>5</sup><https://mahout.apache.org>

We compare the results in relation about two different aspects:

- **Evaluation of preference stability.** We perform the same analysis performed in Section III, and measure the average number of classes involved in our *CPI* models and their *popularity* (i.e., how many positive preferences are associated to each class). The objective is to understand how capable our modeling approach is at reducing the effects of preference stability (which, as highlighted in the Introduction, introduces overspecialization problems), by extending the ground truth;
- **Evaluation of the classes included in the model.** In order to evaluate the significance of the produced models, we evaluate the overlap between the classes produced by the *CPI* model and the classes involved in the items recommended by SVD++, by measuring the Jaccard index between the sets  $C_u$  and  $CPI_u$ .

### C. Metrics

The *popularity* metric, which allows to measure preference stability, was already introduced in Section III (Equation 2). The evaluation of the classes included in the model has been performed by measuring the *Jaccard* index, in order to measure the overlap between the classes included in our *CPI* model (denoted as  $C_u(CPI)$ ), and those that classify the items recommended by SVD++ (denoted as  $C_u(SDV++)$ ):

$$J(C_u(CPI), C_u(SDV++)) = \frac{|C_u(CPI) \cap C_u(SDV++)|}{|C_u(CPI) \cup C_u(SDV++)|} \quad (7)$$

During this operation we considered the three most relevant classes identified by the two approaches.

### D. Experimental Results

This section presents the results obtained by the two evaluations previously presented.

1) *Evaluation of preference stability:* Fig. 3 shows preference stability for both approaches. The results show that the effect of preference stability is strongly reduced by our approach. In fact the number of classes involved in the model is now 10 (remember that in Section III we showed that user preferences were distributed over 6 classes). This shows an important first result, which is the capability of our approach to extend the ground truth and to be able to characterize user preferences over a larger set of classes, without considering the preferences of the other users. By enlarging the set of classes, we can also see that the *popularity* of each class (i.e., the number of preferences expressed for the items that belong to a class), is also strongly reduced; indeed, we move from 46% of preferences that characterize the main class of each user to a 27.2% value. We can also notice that the amount of classes inferred by our model that has a *popularity*  $\geq 1\%$  is exactly the same available in the  $C_u(SDV++)$  models. This means that our approach is able to characterize user preferences in terms of classes without producing any comparison with the preferences of the other users, thus strongly reducing the computational load necessary to infer what a user is going to like.

Fig. 3: Class Distribution by Popularity

2) *Evaluation of the classes included in the model:* The previous analysis showed that the number of classes involved in our *CPI* models is the same of those produced by the *SVD++* predictions. However, this result is not enough to validate our model, as the two sets of classes might be completely different. For each user we measured the Jaccard index on the sets of classes and averaged the obtained values. The average value of all results is 0.8218, which demonstrates that the most popular classes recommended through our *CPI* model are almost the same of the *SVD++* approach. This demonstrates that in spite its simplicity, the *CPI* approach operates within the same range of items of a canonical approach at the state-of-the-art.

## VI. RELATED WORK

Likewise to other contexts, in recommender systems the preferences of the users about new choices (goods or services) tend to follow the behavior of the other users with similar tastes. This is a well-known phenomenon, called *homophily*, that in the recommender systems environment is embraced by the most common strategies used to recommend new items (e.g., *content-based* [10] and *collaborative-filtering* [26], [27] approaches). If on the one hand this approach leads toward items of likely interest to users, on the other hand it reduces the range of items of potential interest that a system could recommend, augmenting the serendipity problem, in a scenario known as the *filter bubble* [16]. The *serendipity* problem, i.e., the ability for a recommender system to suggest items of potential interest to the user that are not trivial, i.e., too similar to those in a user profile. In some works, such as [9], *serendipity* is briefly described as *a measure of how surprising the successful recommendations are*. The same work discusses the *serendipity* as the deviation from the *natural* prediction [28], and introduces the opportunity to estimate an optimal deviation value to use in order to make recommendations, underlining the risk related to an inappropriate measurement, which can lead toward a loss of user trust in regard to the recommendation system. A disadvantage that affects those recommender systems that take into account the diversity [29], is that they still operate within the classes of items for which users have expressed an explicit liking.

Another well-known problem is the so called *selective exposure*, i.e., the tendency of users to make their choices (goods or services) based only on their usual preferences, a

typical way to proceed that excludes the possibility for the users to find new items that may be of interest to them [30]. The literature presents several approaches that try to reduce this problem, e.g., the *NewsCube* [31] that operates offering to the users several points of views, in order to stimulate them to make different and not usual choices.

In order to represent the user preferences and improve the effectiveness of the suggestions, in the literature we can find several approaches. For instance, users can be classified based on some explicit features (e.g., their demographic data) by extracting this information from sources such as Twitter [32], or based on other implicit features extracted through a more complex analysis of the same sources [33]. In [34], an approach to preprocess the users profiles in order to detect and remove the items that generate noise and could make the profiles not adherent to the real tastes of the users is also presented.

The *serendipity* problem shows that a challenge in this area is then to identify a method able to make effective predictions, exploiting not only the information present in the user profiles. Our approach faces this problem by introducing a new modeling approach based on the class of items instead of considering the items. This is a new strategy of classification based on the classes that extends the set of possible items to recommend, taking also into account those distant from the previous choices of the users, although within their favorite classes of items. The use of a *class-based* model is also able to reduce the entity of the *selective exposure* problem, because it selects the items within a broader set of classes.

## VII. CONCLUSIONS AND FUTURE WORK

In this paper we proposed a new approach that models user preferences in terms of classes. Our approach is based on a semantic analysis that performs a matching operation over the semantic relations (synsets) that characterize the items of a class and those that characterize the items a user prefers. In order to do so, we generate a set of binary filters (called *Semantic Binary Sieves*) that characterize each class, and that are used to build a relevance score of that class for the users. The relevance scores are combined in a ranked list of classes, called *Class Path Information* model.

Experimental results showed the capability of our approach to extend the ground truth and infer where the future preferences of the users will go. Indeed, by comparing our models with the set of classes of the items predicted by a state-of-the-art recommender system, we highlighted a strong overlap between them. This means that our approach is able to accurately infer user preferences in terms of classes, and that the generated models can be employed by a recommender system to select items within the set of classes included in the model. The advantages are both on the computational load, since the system avoids calculating the semantic distance between the items, and on the possibility to recommend items that are not too dissimilar to those she/he already positively evaluated.

Future work will investigate the effectiveness of our modeling technique at supporting a recommender system to produce serendipitous item recommendations. The idea is to produce the recommendations considering the classes available in the

model, which are semantically related to the items a user likes, but are not the same. This would allow us to produce serendipity, without the negative consequences caused by diversity.
